In order to understand the material dependence of T_c within the single-layered cuprates, we study a two-orbital model that considers both $d_{x^2-y^2}$ and d_{z^2} orbitals. We reveal that a hybridization of d_{z^2} on the Fermi surface substantially affects T_c in the cuprates, where the energy difference ΔE between the d_{x^2-y2} and d_{z^2} orbitals is identified to be the key parameter that governs both the hybridization and the shape of the Fermi surface. A smaller ΔE tends to suppress T_c through a larger hybridization, whose effect supersedes the effect of diamond-shaped (better-nested) Fermi surface. The mechanism of the suppression of d-wave superconductivity due to d_{z^2} orbital mixture is clarified from the viewpoint of the ingredients involved in the Eliashberg equation, i.e., the Green's functions and the form of the pairing interaction described in the orbital representation. The conclusion remains qualitatively the same if we take a three-orbital model that incorporates Cu 4s orbital explicitly, where the 4s orbital is shown to have an important effect of making the Fermi surface rounded. We have then identified the origin of the material and lattice-structure dependence of ΔE, which is shown to be determined by the energy difference ΔE_d between the two Cu3d orbitals (primarily governed by the apical oxygen height), and the energy difference ΔE_p between the in-plane and apical oxygens (primarily governed by the interlayer separation d).

I. INTRODUCTION

Despite the fact that the history of the high-T_c cuprates exceeds two decades, there remain a number of fundamental questions which are yet to be resolved. Among them is the significant variation of T_c among various materials within the cuprate family. It is well known that T_c varies strongly with the number of CuO_2 layers, but an even more basic problem is the T_c variation within the single-layered materials. This is highlighted by $La_{2-x}(Sr/Ba)_xCuO_4$ with a $T_c \simeq 40$ K versus $HgBa_2CuO_{4+\delta}$ with a $T_c \simeq 90$K, with a more than factor of two difference despite similar crystal structures between them.

Empirically, it has been recognized that the materials with $T_c \sim 100$K tend to have "round" Fermi surfaces, while the Fermi surface of the La system is closer to a diamond shape, and this has posed a long-standing, big puzzle, since, the latter would imply a relatively better nesting[1, 2]. The materials with rounded Fermi surfaces conventionally have been analyzed with a single-band model with large second ($t_2(>0)$) and third ($t_3(<0)$) neighbor hopping integrals, while the "low-T_c" La system has been considered to have smaller t_2, t_3. This, however, has brought about a contradiction between theories and experiments. Namely, while some phenomenological[3] and t-J model[4, 5] studies give a tendency consistent with the experiments, a number of many-body approaches for the *Hubbard-type* models with realistic values of on-site interaction U show suppression of superconductivity for large $t_2 > 0$ and/or $t_3 < 0$, as we shall indeed confirm below[6].

To resolve this discrepancy, we have introduced in ref.[7] a two-orbital model that explicitly incorporates the d_{z^2} orbital as well, while the usual wisdom was that the $d_{x^2-y^2}$ orbital suffices. The former component has in fact a significant contribution to the Fermi surface in the La system. We have shown that the key parameter that determines T_c is the hybridization of the two-orbitals, which is in turn governed by the level offset ΔE between the $d_{x^2-y^2}$ and d_{z^2} Wannier orbitals. Namely, the weaker the d_{z^2} contribution to the Fermi surface, the better for d-wave superconductivity, where a weaker contribution of the d_{z^2} results in a rounded Fermi surface (which in itself is not desirable for superconductivity), but it is the "single-orbital nature" that favors a higher T_c superseding the effect of the Fermi surface shape. Recently, there have also been some other theoretical studies regarding the role of the d_{z^2} orbital played in the cuprates[8–11].

Purpose of the present paper is two-fold: By elaborating the two-orbital model, we investigate (i) why the d_{z^2} hybridization on the Fermi surface suppresses the superconductivity, and (ii) what are the key components that determine the material dependence in the level offset between $d_{x^2-y^2}$ and d_{z^2}. In examining point (ii), in addition to La_2CuO_4 and $HgBa_2CuO_{4+\delta}$ considered in ref.[7], we also construct effective models of the single-layered cuprates $Bi_2Sr_2CuO_6$ and $Tl_2Ba_2CuO_6$ to reveal how these materials can be classified in terms of the correlation between the lattice structure parameters and the level offsets of various orbits.

II. CONSTRUCTION OF THE TWO-ORBITAL MODEL

A. Band calculation

Let us start with the first-principles band calculation[12] of La_2CuO_4 and $HgBa_2CuO_4$, whose band structures are displayed in Fig.1. The lattice parameters adopted here are experimentally determined ones for the doped materials[13, 14]. In both cases, there is only one band intersecting the Fermi level. Therefore, the $d_{x^2-y^2}$ single-orbital Hubbard model, or the Cu-$d_{x^2-y^2}$ + O-p_σ three-orbital model (whose antibonding band crosses the Fermi level) has been adopted in conventional theoretical studies. A large difference between the two materials in the shape of the Fermi surface is confirmed in Fig.2. As mentioned in the Introduction, the materials with a rounded Fermi surface have been modeled by a single-orbital model with large second $[t_2(>0)]$ and third $[t_3(<0)]$ neighbor hopping integrals[1]. It has been noticed that when the fluctuation exchange approximation (FLEX)[15, 16] is applied to this model, a rounder Fermi surface coming from larger second and third neighbor hoppings results in a suppressed T_c, as we have shown in Fig.1 of ref.7. A calculation with the dynamical cluster approximation (DCA) shows that a negative t_2 works destructively against d-wave superconductivity[17], and a more realistic DCA calculation that considers the oxygen p_σ orbitals for the La and Hg cuprates also indicates a similar tendency[18].

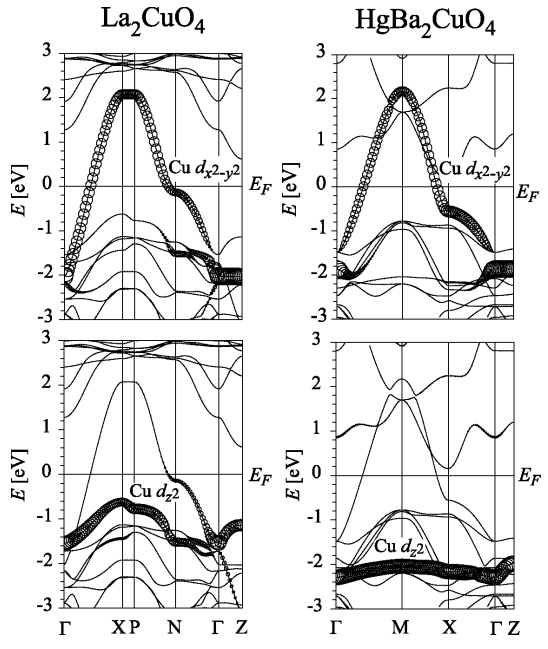

FIG. 1: First-principles band structures of La_2CuO_4 (left) and $HgBa_2CuO_4$ (right). The top (bottom) panels depict the strength of the $d_{x^2-y^2}$ (d_{z^2}) characters with the radius of the circles.

B. The two-orbital model

To resolve the above problem for the $d_{x^2-y^2}$ single-orbital model, we now focus on other orbital degrees of freedom. In fact, Fig.1 shows that in the La system the main band has a strong d_{z^2} character around the N point on the Fermi surface that corresponds to the wave vectors $(\pi, 0), (0, \pi)$ in a square lattice. This has been recognized from an early stage of the study on the cuprates [19–22], and more recently, it has been discussed in refs.[1, 23] that the mixture of d_{z^2} character to the main component determines the shape of the Fermi surface. Namely, the large d_{z^2} contribution in the La system makes the Fermi surface closer to a square (i.e., a diamond), while in the Hg cuprate the d_{z^2} contribution is small and the Fermi surface is more rounded (as confirmed in the following).

In order to understand the experimentally observed correlation between the Fermi surface shape and T_c, we consider a two-orbital model that takes into account not only the $d_{x^2-y^2}$ Wannier orbital but also the d_{z^2} Wannier orbital explicitly[7]. A first-principles calculation[12, 24] is used to construct maximally localized Wannier orbitals[25, 26], from which the hopping integrals and the on-site energies of the two-orbital tight-binding model for the La and Hg cuprates are deduced. Thus obtained band structures of the two-orbital model for the La and Hg cuprates are shown in Fig.3, along with the Fermi surface for the band filling of $n = 2.85$ (n =number of electrons per site), which corresponds to 0.15 holes per Cu atom.

In the present two-orbital model, the $d_{x^2-y^2}$ Wannier orbital originates primarily from the Cu $3d_{x^2-y^2}$ and the in-plane O $2p_\sigma$ orbitals. On the other hand, the d_{z^2} Wannier orbital originates mainly from the Cu $3d_{z^2}$ and apical O $2p_z$ orbitals. Namely, this model incorporates two types of d-p_σ antibonding states, where the former spreads over the CuO_2-plane while the latter along the c-axis(Fig.4). TableI shows the parameter values of the present model, from which we can identify that $d_{x^2-y^2} - d_{z^2}$ interorbital hopping occurs mainly between nearest-neighbor Cu sites, which gives rise to the orbital mixture. Because the $d_{x^2-y^2} - d_{z^2}$ hopping integrals are similar for the La and Hg compounds, the onsite energy difference $\Delta E = E_{x^2-y^2} - E_{z^2}$ between the two orbitals can be used as a measure of the d_{z^2} mixture. Note that

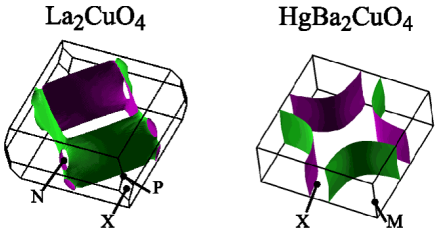

FIG. 2: (Color online) The Fermi surface of the La_2CuO_4 (left) and $HgBa_2CuO_4$ (right) with 0.15 holes/Cu atom.

the interorbital hoppings have different signs between x and y directions, i.e., the matrix element has the form $-2t_1[\cos(k_x)-\cos(k_y)]$, so that the $d_{x^2-y^2}-d_{z^2}$ mixture is strong around the wave vectors $(\pi,0),(0,\pi)$ (N point in the La cuprate), while small around $|k_x|=|k_y|$.

In TableI we also show the parameters for the single-orbital model obtained by the similar method. In the single-orbital model, the "$d_{x^2-y^2}$" Wannier orbital effectively contains the d_{z^2} orbital in the tail parts of the Wannier orbital.

C. Correlation between the curvature of the Fermi surface and ΔE

The d_{z^2} orbital contribution has also a large effect on the curvature of the Fermi surface[1, 23], which can indeed be seen from TableI as follows. In the single-orbital model, the La cuprate has smaller t_2 and t_3 as compared to the Hg cuprate (with the ratio $(|t_2|+|t_3|)/|t_1|$ being 0.14(0.37) for La(Hg)), resulting in the smaller curvature of the Fermi surface in the former as mentioned. On the other hand, in the two-orbital model that considers the d_{z^2} orbital explicitly, the ratio $(|t_2|+|t_3|)/|t_1|$ within the $d_{x^2-y^2}$ orbital changes to 0.35(0.41) for the La(Hg). The value is nearly the same between the single- and two-orbital modelling of Hg, while the value is significantly increased in the two-orbital model for La. The reason why t_2 and t_3 in the two-orbital model for La is large as compared to that in the single-orbital model can be understood from Fig.5 as follows. Let us consider the diagonal hopping (t_2). There is a direct $(d_{x^2-y^2}-d_{x^2-y^2})$ diagonal hopping, but there is also an indirect diagonal hopping that becomes effective when ΔE is small,

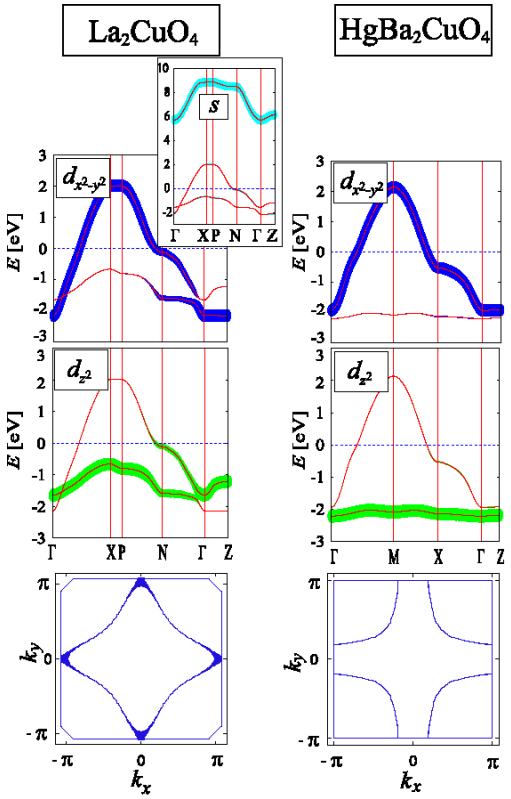

FIG. 3: (Color online) The band structure (with $E_F=0$) in the two-orbital ($d_{x^2-y^2}$-d_{z^2}) model for La_2CuO_4 (left column) and $HgBa_2CuO_4$ (right). The top (middle) panels depict the weights of the $d_{x^2-y^2}$ (d_{z^2}) characters with thickened lines, while the bottom panels are the Fermi surface for the band filling of $n=2.85$. The inset shows the band structure of the three-orbital model (see text) for La system, where the 4s character is indicated by thick lines.

TABLE I: Hopping integrals within the $d_{x^2-y^2}$ orbital for the single- and two-orbital models (upper half), interorbital hopping (middle), and $\Delta E \equiv E_{x^2-y^2}-E_{z^2}$ (bottom).

	1-orbital		2-orbital

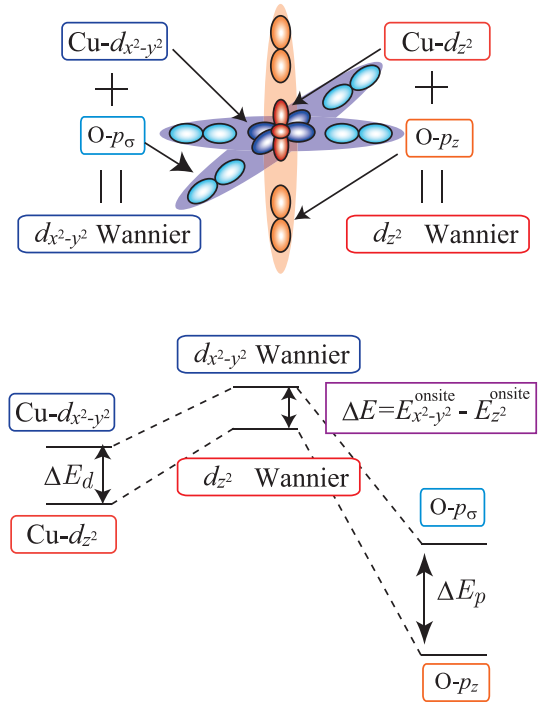

FIG. 4: (Color online) The top panel shows the main components of the two Wannier orbitals (having different types of σ bonding) considered in the present two-orbital model. The bottom panel shows the definition of the level offsets ΔE, ΔE_d, and ΔE_p.

that is, $d_{x^2-y^2} \rightarrow d_{z^2} \rightarrow d_{x^2-y^2}$. In the single-orbital model, where the d_{z^2} component is effectively included in the $d_{x^2-y^2}$ Wannier orbital, the contribution of the $d_{x^2-y^2} \rightarrow d_{z^2} \rightarrow d_{x^2-y^2}$ path is effectively included in t_2. The latter contribution has a sign opposite to that of the direct diagonal hopping (the reason of which will be clarified later), so that we end up with a small effective t_2 in the single-orbital model when ΔE is small as in the La cuprate. A similar argument applies to t_3. Conversely, the Hg cuprate has a large ΔE so that the d_{z^2} contribution barely exists in the single-orbital model, and the ratio $(|t_2| + |t_3|)/|t_1|$ is similar to that in the two-orbital model.

In the La cuprate, the $d_{x^2-y^2}$ and d_{z^2} orbitals strongly mix around the N point, so that the upper and lower bands repel with each other there, and the saddle point of the upper band that corresponds to the van Hove singularity is pushed up to nearly touch the Fermi level for the band filling of $n = 2.85$. Thus the Fermi surface almost touches the wave vectors $(\pi, 0)$, $(0, \pi)$. In the Hg cuprate, there is no such splitting of the two bands, and the saddle point stays well below the Fermi level, resulting in a rounded Fermi surface that is closed around the wave vector (π, π).

III. MANY-BODY CALCULATION OF THE SUPERCONDUCTIVITY

A. Calculation method

We now consider a many-body Hamiltonian based on the two-orbital tight-binding model discussed above, which is given, in the standard notation, as

$$\begin{aligned} H &= \sum_i \sum_\mu \sum_\sigma \varepsilon_\mu n_{i\mu\sigma} + \sum_{ij} \sum_{\mu\nu} \sum_\sigma t_{ij}^{\mu\nu} c_{i\mu\sigma}^\dagger c_{j\nu\sigma} \\ &+ \sum_i \Bigg(U \sum_\mu n_{i\mu\uparrow} n_{i\mu\downarrow} + U' \sum_{\mu>\nu} \sum_{\sigma,\sigma'} n_{i\mu\sigma} n_{i\mu\sigma'} \\ &- \frac{J}{2} \sum_{\mu\neq\nu} \sum_{\sigma,\sigma'} c_{i\mu\sigma}^\dagger c_{i\mu\sigma'} c_{i\nu\sigma'}^\dagger c_{i\nu\sigma} \\ &+ J' \sum_{\mu\neq\nu} c_{i\mu\uparrow}^\dagger c_{i\mu\downarrow}^\dagger c_{i\nu\downarrow} c_{i\nu\uparrow} \Bigg), \end{aligned} \tag{1}$$

where i, j denote the sites and μ, ν the two-orbitals, while the electron-electron interactions comprise the intraorbital repulsion U, interorbital repulsion U', and the Hund's coupling J(= pair-hopping interaction J'). Here we take $U = 3.0$ eV, $U' = 2.4$ eV, and J=0.3 eV[27]. These values conform to a widely accepted, first-principles estimations for the cuprates that the U is 7-10t (with $t \simeq 0.45$ eV), while $J, J' \simeq 0.1U$. Here we also observe the orbital SU(2) requirement $U' = U - 2J$.

To study the superconductivity in this multi-orbital Hubbard model, we apply FLEX approximation[15, 16, 28]. In FLEX, we start with the Dyson's equation to obtain the renormalized Green's function, which, in the multi-orbital case, is a matrix in the orbital representation as $G_{l_1 l_2}$, where l_1 and l_2 are orbital indices. The bubble and ladder diagrams consisting of the renormalized Green's function are then summed to obtain the spin and charge susceptibilities,

$$\hat{\chi}_s(q) = \frac{\hat{\chi}^0(q)}{1 - \hat{S}\hat{\chi}^0(q)}, \tag{2}$$

$$\hat{\chi}_c(q) = \frac{\hat{\chi}^0(q)}{1 + \hat{C}\hat{\chi}^0(q)}, \tag{3}$$

where $q \equiv (\vec{q}, i\omega_n)$, the irreducible susceptibility is

$$\chi^0_{l_1,l_2,l_3,l_4}(q) = \sum_q G_{l_1 l_3}(k+q) G_{l_4 l_2}(k), \tag{4}$$

with the interaction matrices

$$S_{l_1 l_2, l_3 l_4} = \begin{cases} U, & l_1 = l_2 = l_3 = l_4 \\ U', & l_1 = l_3 \neq l_2 = l_4 \\ J, & l_1 = l_2 \neq l_3 = l_4 \\ J', & l_1 = l_4 \neq l_2 = l_3, \end{cases} \tag{5}$$

$$C_{l_1 l_2, l_3 l_4} = \begin{cases} U & l_1 = l_2 = l_3 = l_4 \\ -U' + J & l_1 = l_3 \neq l_2 = l_4 \\ 2U' - J, & l_1 = l_2 \neq l_3 = l_4 \\ J' & l_1 = l_4 \neq l_2 = l_3. \end{cases} \quad (6)$$

With these susceptibilities, the fluctuation-mediated effective interactions are obtained, which are used to calculate the self-energy. Then the renormalized Green's functions are determined self-consistently from the Dyson's equation. The obtained Green's functions and the susceptibilities are used to obtain the spin-singlet pairing interaction in the form

$$\hat{V}^s(q) = \frac{3}{2}\hat{S}\hat{\chi}_s(q)\hat{S} - \frac{1}{2}\hat{C}\hat{\chi}_c(q)\hat{C} + \frac{1}{2}(\hat{S} + \hat{C}), \quad (7)$$

and this is plugged into the linearized Eliashberg equation,

$$\lambda\Delta_{ll'}(k) = -\frac{T}{N}\sum_q \sum_{l_1 l_2 l_3 l_4} V_{ll_1 l_2 l'}(q) \times G_{l_1 l_3}(k-q)\Delta_{l_3 l_4}(k-q)G_{l_2 l_4}(q-k). \quad (8)$$

The superconducting transition temperature, T_c, corresponds to the temperature at which the eigenvalue λ of the Eliashberg equation reaches unity, so that λ at a fixed temperature can be used as a measure for T_c. In the present calculation, the temperature is fixed at $k_B T = 0.01$ eV, which amounts to about 100K, and the band filling (number of electrons/site) is set to be $n = 2.85$, which corresponds to 0.85 electrons per site in the main band, namely, around the optimum doping concentration. We take $32 \times 32 \times 4$ k-point meshes and 1024 Matsubara frequencies.

B. Correlation between T_c and ΔE

Let us now investigate how the d_{z^2} orbital affects superconductivity by hypothetically varying ΔE from its original value 0.91 eV (shown in TableI) to 4.0 eV for the La cuprate to single out the effect of ΔE. The eigenvalue of the Eliashberg equation λ calculated as a function of ΔE in Fig.6 shows that λ initially increases rapidly upon increasing ΔE, then saturates for $\Delta E > 3$eV. This means that the mixture of the d_{z^2} orbital on the Fermi surface around the wave vectors $(\pi, 0)$, $(0, \pi)$ does indeed strongly suppress superconductivity in the original La system, while for large enough ΔE the system essentially reduces to a single-orbital model, where d_{z^2} orbital no longer affects superconductivity. As mentioned above, the d_{z^2} orbital mixture makes the Fermi surface more square shaped, which in itself favors superconductivity as mentioned in sectionII A (e.g., Fig.1 of ref.7). Thus we can see that the effect of the d_{z^2} orbital mixture *supersedes* the effect of Fermi surface shape, and T_c is primarily determined by the former. This explains why we have T_c positively correlated with ΔE simultaneously with the roundness of the Fermi surface that is also positively correlated with ΔE. This should lead to the experimentally observed correlation between the shape of the Fermi surface and T_c[1, 2].

C. Effects of the inter-orbital electron-electron interaction

Thus the next important question is: why does the mixture of the d_{z^2} orbital on the Fermi surface suppress superconductivity? To investigate the origin, we have varied the interaction values to examine the strength of the spin fluctuations and the superconducting instability. The strength of the spin fluctuation is measured by the antiferromagnetic Stoner factor, which, for a multiband system, corresponds to the largest eigenvalue of the matrix $\hat{S}\chi_0$.

In the result in TableII we can compare the cases for $U' = 0$ eV and $U' = 2.4$ eV, which shows that the strength of the spin fluctuation becomes smaller when U' is turned off. This should be because U' hinders four electrons (two d_{z^2} and two $d_{x^2-y^2}$) to come on the same site. Despite this, it can be seen that λ is not much affected by U', probably because the suppression of superconductivity due to the increased charge/orbital fluctuations (which is unfavorable for singlet d-wave pairing) and the enhancement due to the increased spin fluctuations roughly cancel with each other. We have also examined how the Hund's coupling J affects superconductivity. A comparison between $J = 0$ and $J = 0.3$ shows that superconductivity is slightly suppressed when we turn on J, which is consistent with an observation that the Hund's coupling tends to suppress spin-singlet pair-

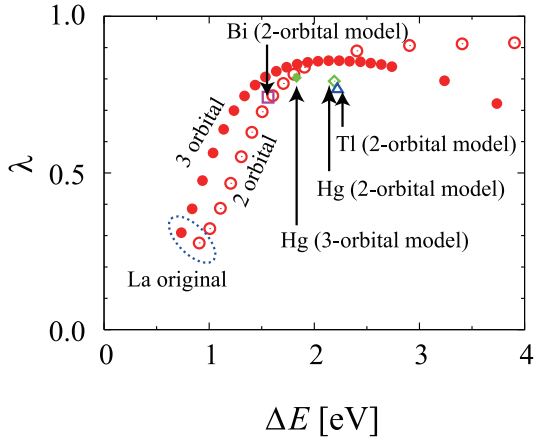

FIG. 6: (Color online) The eigenvalue, λ, of the Eliashberg equation for d-wave superconductivity plotted against $\Delta E = E_{x^2-y^2} - E_{z^2}$ for the two-orbital (red open circles) and three-orbital (red filled circles) models for La_2CuO_4. Corresponding eigenvalues for $HgBa_2CuO_4$,$Bi_2Sr_2CuO_6$ and $Tl_2Ba_2CuO_6$ are also indicated.

ing. Nevertheless, the effect of J is overall small. The conclusion here is that the effect of the interorbital interactions on superconductivity is small, so that the main origin of the suppression of superconductivity is the mixture of the d_{z^2} orbital on the Fermi surface, which will be elaborated in the next subsection.

TABLE II: FLEX result for the eigenvalue of the Eliashberg equation λ, and the Stoner factor for various values of the interorbital interactions U' and J, for fixed $U = 3.0$ eV and $J' = 0.30$ eV

U'[eV]	J[eV]	Stoner	λ
2.4	0.3	0.979	0.279
2.4	0.0	0.978	0.335
0.0	0.3	0.925	0.291
0.0	0.0	0.958	0.309

D. Origin of the suppression of superconductivity by the d_{z^2} mixing

Here we pinpoint why the d_{z^2} orbital component mixture degrades d-wave superconductivity. In Fig.7, we show the squared orbital diagonal and off-diagonal elements of the Green's function matrix spanned by the orbital indices at the lowest Matsubara frequency. We compare them for two cases; the original La cuprate and a hypothetical case where we increase ΔE to the value for Hg, where the hopping integrals are tuned to retain the shape of the Fermi surface to that of the La cuprate. In the hypothetical case, the interaction values are reduced ($U = 2.1$ eV, $J = J' = 0.1U$ and $U' = U - 2J$) so as to make the maximum value of the pairing interaction in the $d_{x^2-y^2}$ channel (V_{1111}) to be roughly the same as that in the original La case. Then the eigenvalues of the Eliashberg equation at $T = 0.01$ differ as much as $\lambda = 0.28$ and 0.88 for the original La and the hypothetical cases, respectively. Let us analyze the origin of this difference. Here we denote the $d_{x^2-y^2}$ and d_{z^2} orbitals as orbitals 1 and 2, respectively. In the original La, compared to the hypothetical case, (i) the $d_{x^2-y^2}$ diagonal element $|G_{11}|^2$ is smaller especially around the wave vectors $(\pi, 0)/(0, \pi)$, (ii) the d_{z^2} diagonal element $|G_{22}|^2$ is much larger, and (iii) there is a substantial off-diagonal element $|G_{12}|^2$ due to the strong d_{z^2} orbital mixture. If we turn to the pairing interaction matrix, again at the lowest Matsubara frequency, in Fig.8, the diagonal elements have similar maximum values between the two cases because the interaction is reduced in the hypothetical one as mentioned above. In the original La, the off-diagonal element of the pairing interaction V_{1221} is large compared to the hypothetical case, and the interaction is broadly peaked around $(0, 0)$. On the other hand, the d_{z^2} diagonal interaction V_{2222} is finite but has a small momentum dependence. Considering the above, the dominant contributions to the Eliashberg equation regarding the $d_{x^2-y^2}$ orbital component of the gap function Δ_{11} is roughly given as

$$\begin{aligned} &\lambda\Delta_{11}(k) \sim \\ &- V_{1111}(Q)G_{11}(k-Q)\Delta_{11}(k-Q)G_{11}(Q-k) \\ &- V_{1221}(0,0)G_{21}(k)\Delta_{11}(k)G_{21}(-k) \\ &- \sum_q V_{2222}(q)G_{22}(k-q)\Delta_{22}(k-q)G_{22}(q-k), \end{aligned} \quad (9)$$

where $\vec{Q} = (\pi, \pi)$. If we consider a wave vector $\vec{k}$ near $(\pi, 0)$ on the Fermi surface that has a positive $\Delta_{11}(k)$, $\Delta_{11}(k-Q)$ will be negative for the d-wave gap. Then the first term on the right-hand side will be positive but small in the original La compared to the hypothetical case because of the small G_{11} especially around $(\pi, 0)/(0, \pi)$. This is the main reason why λ is reduced in the original La compared to the hypothetical case. In addition, the second term, which cannot be neglected when the d_{z^2} mixture is significant, actually has a negative sign, and also acts to suppress λ and hence T_c. The interaction V_{2222} has small momentum dependence, so that this term has small contribution for a d-wave gap when summed over q.

In the above comparison, we have reduced the interactions in the hypothetical case so as to make the maximum pairing interaction V_{1111} nearly the same as in the original La. The reason we fix the strength of the pairing interaction is because the maximum value of the pairing interaction actually does not differ very much upon increasing ΔE in the results given in Fig.6. The reason for this, despite the Fermi surface nesting becoming worse as we increase ΔE, is mainly two-fold: (i) the d_{z^2} orbital mixture on the Fermi surface becomes weaker, and (ii) inclusion of the self-energy in the FLEX weakens the role of the Fermi surface nesting played in the development of the spin fluctuations. Regarding the second point, in the random phase approximation where the self-energy is not considered, the Fermi surface nesting effect on the strength of the spin fluctuations, hence the pairing interaction, is so strong that λ does not increase with ΔE as in Fig.6 (and thus the T_c difference between La and Hg cuprates discussed later cannot be explained), although the effect of the increase in G_{11} due to the reduction of the d_{z^2} mixture is present. This may be regarded as consistent with a recent result obtained with the functional renormalization group, where the self-energy correction is not considered[11].

E. $d_{x^2-y^2} + d_{z^2} + s$ three-orbital model

So far we have analyzed the two-orbital model that considers the $d_{x^2-y^2}$ and d_{z^2} Wannier orbitals. Actually in ref.[1, 23], it has been pointed out that the "axial state" that contains not only Cu d_{z^2} and $O_{\rm apical}p_z$ orbital but also the Cu-4s orbital is important in determining the shape of the Fermi surface. In the present two-orbital model, the Cu 4s orbital is effectively incorporated in both of the $d_{x^2-y^2}$ and d_{z^2} Wannier orbitals.

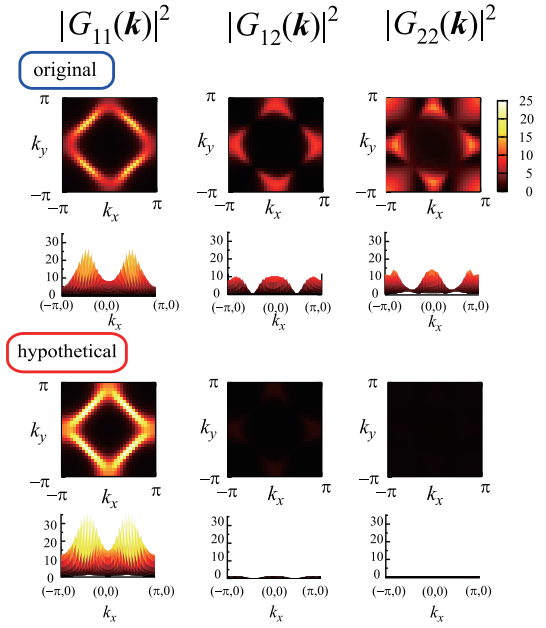

FIG. 7: (Color online) Contour plots and side views of the diagonal and off-diagonal elements of the squared Green's function for the original La and the hypothetical cases. The subscripts 1 and 2 stand for the $d_{x^2-y^2}$ and d_{z^2} orbitals, respectively.

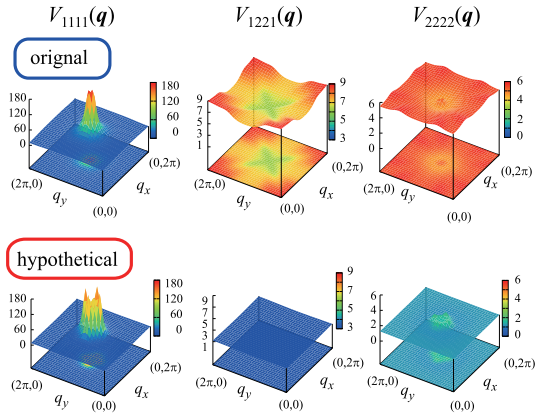

FIG. 8: (Color online) Diagonal and off-diagonal elements of the pairing interaction depicted against (q_x, q_y).

Namely, the Wannier orbitals have Cu $4s$ components in their tails. In order to examine the effect of Cu $4s$ orbital more explicitly, let us consider in this section a $d_{x^2-y^2}+d_{z^2}+s$ three-orbital model which takes into account the Cu-$4s$ Wannier orbital on an equal footing.

In this model, the $4s$ Wannier orbital is a mixture mainly of Cu $4s$ and O p_σ orbitals. The O p_σ orbitals contain not only the in-plane $O_{\rm plane}p_\sigma$ but also the apical $O_{\rm apical}p_z$. The main band originating from the 4s orbital for the La system is shown in the inset of Fig3. While the $4s$ band lies well($\simeq$ 7 eV) above the Fermi level, the $4s$ orbital still gives an important contribution to the Fermi surface shape. Here again we estimate the ratio $(|t_2|+|t_3|)/|t_1|$ within the $d_{x^2-y^2}$, where we find a much smaller value of 0.10 against 0.35 in the two-orbital model. This means that the large t_2 and t_3 within the $d_{x^2-y^2}$ Wannier orbital in the two-orbital model is mainly due to the $d_{x^2-y^2} \to 4s \to d_{x^2-y^2}$ hopping path (Fig.5, bottom panel), as pointed out in ref.[1]. Then, from the viewpoint of the three-orbital model, t_2 and t_3 in the single-orbital model of La cuprate are small because the $d_{x^2-y^2} \to 4s \to d_{x^2-y^2}$ and $d_{x^2-y^2} \to d_{z^2} \to d_{x^2-y^2}$ contributions nearly cancel with each other. The two effective hoppings have opposite signs because the d_{z^2} level lies below $d_{x^2-y^2}$ while $4s$ lies above.

Now we apply FLEX to this three-orbital model, where we vary $\Delta E = E_{x^2-y^2} - E_{z^2}$ and calculate the eigenvalue of the Eliashberg equation as we did in subsectionIII B. Here, we fix the on-site energy difference $E_s - E_{d_{z^2}}$ at its original value when we vary ΔE, because the three-orbital model for the Hg compound has roughly the same $E_s - E_{d_{z^2}}$ as that of the La compound.

The result is displayed in Fig. 6 as marked with "3-orbital". We recognize that in the small ΔE regime the eigenvalue λ rapidly increases with ΔE as in the two-orbital model. In the large ΔE regime, however, λ tends to decrease rather than to saturate. In this regime, the $4s$ level comes too close to the Fermi level, and strongly deforms the Fermi surface. Nonetheless, considering that even in the case of the Hg compound with a larger ΔE as will be discussed later, ΔE (3-orbital model) is still $\simeq$ 2 eV, i.e., such a suppression of superconductivity due to the $4s$ level coming too close to the Fermi level is not expected in real materials.

Thus we can conclude on the $4s$ orbital that, while this orbital has an important effect on the shape of the Fermi surface, the effect can be included in the two-orbital model, so that the FLEX results for the two- and three-orbital models are similar as far as the $T_c - \Delta E$ relation is concerned (unless we consider unrealistically large ΔE). This is natural in that the level offset $E_{x^2-y^2} - E_{z^2}$ is smaller ($\simeq$ 1 eV) than the electron-electron interaction($\simeq$ 3 eV), while the $E_s - E_{x^2-y^2}$ is much larger ($\simeq$ 7 eV). Hence the $4s$ orbital can effectively be integrated out before the many-body analysis, while the d_{z^2} orbital cannot. In this sense the two-orbital($d_{x^2-y^2} - d_{z^2}$) model suffices for discussing the material dependence of the T_c in the cuprates.

IV. MATERIAL DEPENDENCE OF ΔE

We have seen that the mixture of the d_{z^2} component strongly affects superconductivity, making T_c positively correlated with ΔE. To further endorse this, we have plotted in Fig.6 the eigenvalue λ for the two-orbital models for single-layered cuprates $Bi_2Sr_2CuO_6$[29], $Tl_2Ba_2CuO_6$[30], and $HgBa_2CuO_4$ as well, whose lattice structures are shown in Fig.9. We can see that these materials also fall upon reasonably well on the correlation between λ and ΔE. Thus the next

fundamental question in understanding the material dependence of T_c is: which key factors determine ΔE. This section precisely addresses that question.

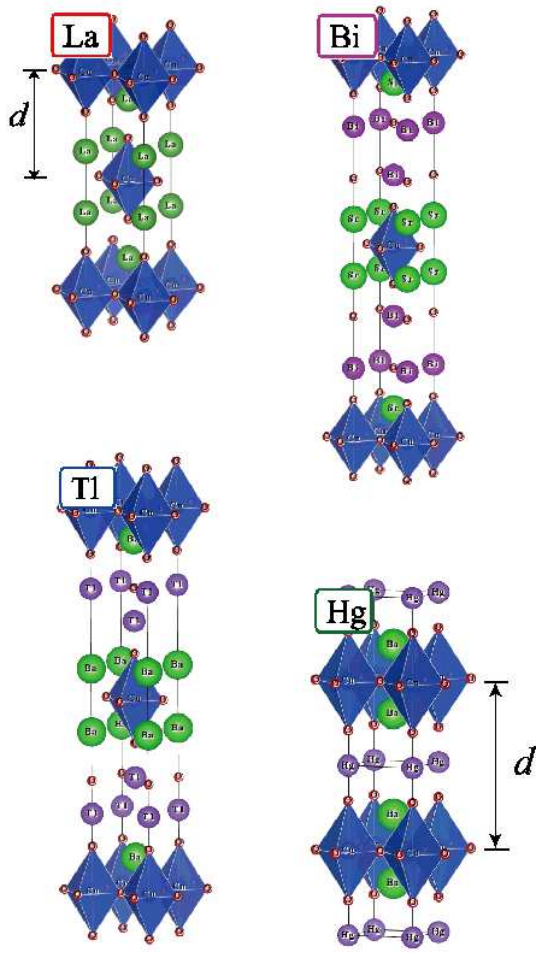

FIG. 9: (Color online) Lattice structures of La_2CuO_4, $Bi_2Sr_2CuO_6$, $Tl_2Ba_2CuO_6$, and $HgBa_2CuO_4$.

A. Crystal-field effect

Since the main components of the Wannier orbitals in the two-orbital model are the Cu $3d_{x^2-y^2}$ and Cu $3d_{z^2}$ orbitals, the crystal-field splitting between these orbitals, denoted as ΔE_d here, should be the first key factor governing ΔE. Namely, materials with a larger apical oxygen height above the CuO_2 plane(h_O) should have a larger crystal-field splitting,[20] so that ΔE_d, and thus ΔE, should be larger (Fig.4). Indeed, the La compound has smaller $h_O = 2.41$ Å and ΔE, while the Hg compound has larger $h_O = 2.78$ Å and ΔE.

So let us first focus on how the apical oxygen height h_O affects ΔE_d. Namely, we construct a model that considers all of the Cu $3d$ and O $2p$ orbitals(five $3d + 3 \times 4$ $2p = 17$ orbitals) explicitly, exploiting maximally localized Wannier orbitals, and then estimate the on-site energy difference between Cu $d_{x^2-y^2}$ and Cu d_{z^2} orbitals as ΔE_d. We note that this ΔE_d is something different from ΔE defined for the effective two-orbital model we have considered, since we now explicitly consider the oxygen $2p$ orbitals. In Fig.10, we plot ΔE_d as a function of h_O, where we hypothetically vary the height for the La system from its original value 2.41 Å to 2.90 Å . The result shows that ΔE_d and h_O are linearly correlated. We have also constructed similar d-p models for the Bi, Tl and Hg systems, and we can see that the ΔE_d values for these materials, also included in the figure, roughly fall upon the linear correlation for the hypothetical La system, which indicates that ΔE_d is primarily determined by h_O. Such a correlation has also been found in a recent quantum chemical calculation[10], where the $d_{x^2-y^2}$-d_{z^2} level splitting evaluated there corresponds more closely to the present ΔE_d rather than ΔE.

Having seen that h_O governs ΔE_d, we next look at ΔE and the eigenvalue λ in the two-orbital models for the La cuprate with hypothetically varied h_O. As expected, ΔE in Fig.11 (b) monotonically increases with h_O. Then λ (Fig.11 (a)) increases with h_O, which is in accord with the positive correlation between ΔE and λ discussed above (Fig.11 (c)). Thus h_O is shown to be one of the key parameters that determine ΔE and thus T_c.

However, if we plot the corresponding values for the Hg cuprate, also displayed in the figure, we find that ΔE, and thus λ, are larger than those for the hypothetical La cuprate for the same apical oxygen height between the two cuprates. This implies that h_O and ΔE_d are not the sole parameters that determine ΔE and hence T_c, and another factor should be lurking.

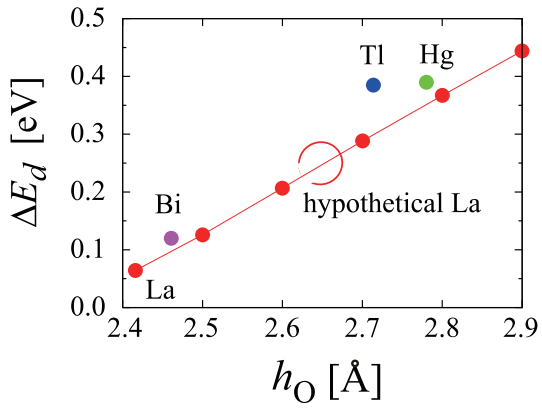

FIG. 10: (Color online) ΔE_d plotted against h_O. Solid (red) circles connected by a line is the result for the hypothetical lattice structure of La cuprate, while values for Bi, Tl and Hg cuprates are also shown.

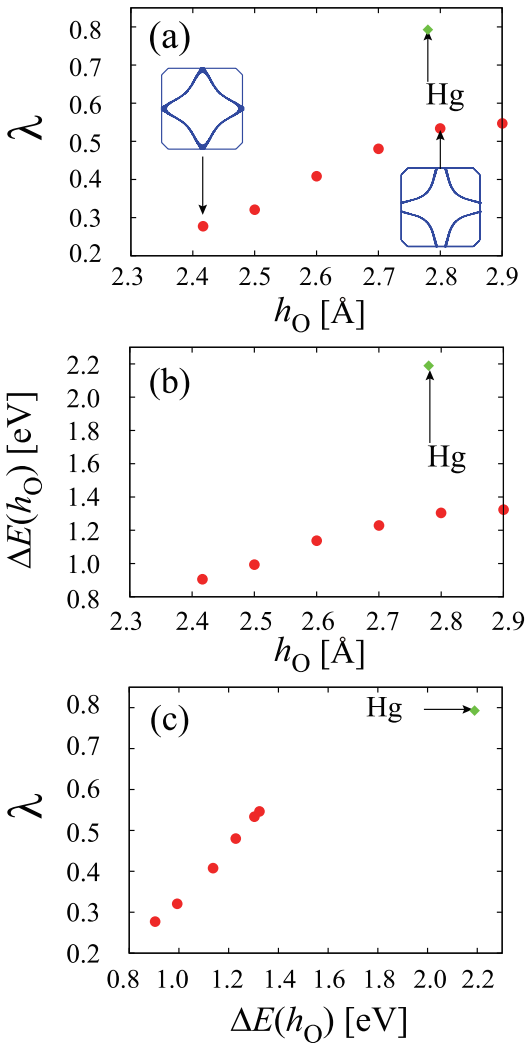

FIG. 11: (Color online) The eigenvalue of the Eliashberg equation λ (circles) when h_O is varied (a) or $\Delta E(h_O)$ is varied (c) hypothetically in the lattice structure of La cuprate. Also plotted is $\Delta E(h_O)$ against h_O(b). Diamonds in green indicate the values for $HgBa_2CuO_4$.

B. Oxygen-orbital effects

The above observation has motivated us to look more closely into the effects of oxygen orbitals. As shown in Fig.4, the Wannier orbitals in our two-orbital model the Cu-$3d_{x^2-y^2}$ and $3d_{z^2}$ orbitals strongly hybridize with the in-plane O $2p_\sigma$ and apical oxygen O $2p_z$ orbitals, respectively. Thus we can surmise that ΔE should also be affected by the energy difference (denoted as ΔE_p) between the in-plain p_σ and the apical oxygen p_z. By definition, one can expect that ΔE_p is positively correlated with ΔV_A, the Madelung potential difference between $O_{\rm plane}$ and $O_{\rm apical}$ introduced by Ohta *et al.* as an important parameter that controls the material dependence of the T_c[31]. In fact, ΔV_A for Hg is about 7 eV larger than that of La, namely, the O-$2p_z$ energy level with respect to the in-plane O-$2p_\sigma$ level is much lower in Hg.

The difference mainly comes from the crystal structure where the apical oxygen in the La cuprate is surrounded by other apical oxygens belonging to the neighboring layers, while in Hg those oxygen atoms are much further apart as seen in Fig.9. This gives a clue to understand the reason why the hypothetical La cuprate with the same h_O as Hg has smaller ΔE and λ; although ΔE_d is similar between the two systems, ΔE_p very much differs. Thus the difference between La and Hg can be attributed to the distance between neighboring CuO_2 layers that is affected by the lattice structure, i.e., body-centered tetragonal (bct) vs. simple tetragonal. However, a similar variance in the layer distance can occur even within similar lattice structures. La, Bi, and Tl compounds all have the bct structures, so naively one might expect similar values of ΔV_A. However, ΔV_A's for Bi and Tl are much larger than that for La. This is because in Bi (Tl) there is a Bi-O (Tl-O) layer inserted between the adjacent CuO_2 layers (see Fig.9), resulting in a large CuO_2 layer separation.

So let us focus on the separation between the neighboring CuO_2 planes, which will be denoted as d here. Figure 12(a) plots $\Delta V_A^{(O_c)}$ against d for La, Hg, Tl, and Bi cuprates. Here we have defined $\Delta V_A^{(O_c)}$ as the contribution to ΔV_A coming from the apical oxygens. These Madelung potentials are calculated by placing point charges at atomic positions, as was done in ref.[31]. We have also plotted the total ΔV_A for the four materials, which indicates that ΔV_A is roughly governed by $\Delta V_A^{(O_c)}$, which in turn is mainly determined by d. We also plot ΔE_p against d in Fig.12(b) for the four cuprates. Here again, ΔE_p is obtained using the model that considers the Cu-3d and O-2p orbitals explicitly. From these we can see that both ΔV_A and ΔE_p are primarily correlated positively with the layer separation d. This in turn implies that ΔE_p and ΔV_A in Fig.12(c) are positively correlated as well.

C. Classification of materials by ΔE_d and ΔE_p

We have seen that ΔE_d and ΔE_p are mainly determined by h_O and d, respectively. Combining these, we can summarize the dependence of ΔE on the material and lattice structure as

$$\Delta E \simeq f(\Delta E_d(h_O), \Delta E_p(d)), \qquad (10)$$

where f is a certain function. For instance, La and Bi have smaller ΔE_d reflecting smaller h_O, while Hg and Tl have larger ΔE_d due to larger h_O. Namely, the latter group tends to have larger ΔE. On the other hand, Bi, Tl, and Hg have larger d than La, so that they have larger ΔV_A. We can summarize all these into a classification of materials in terms of ΔE_d and ΔE_p as a numerical tableIII, and a kind of "phase diagram" in Fig.13. Apart

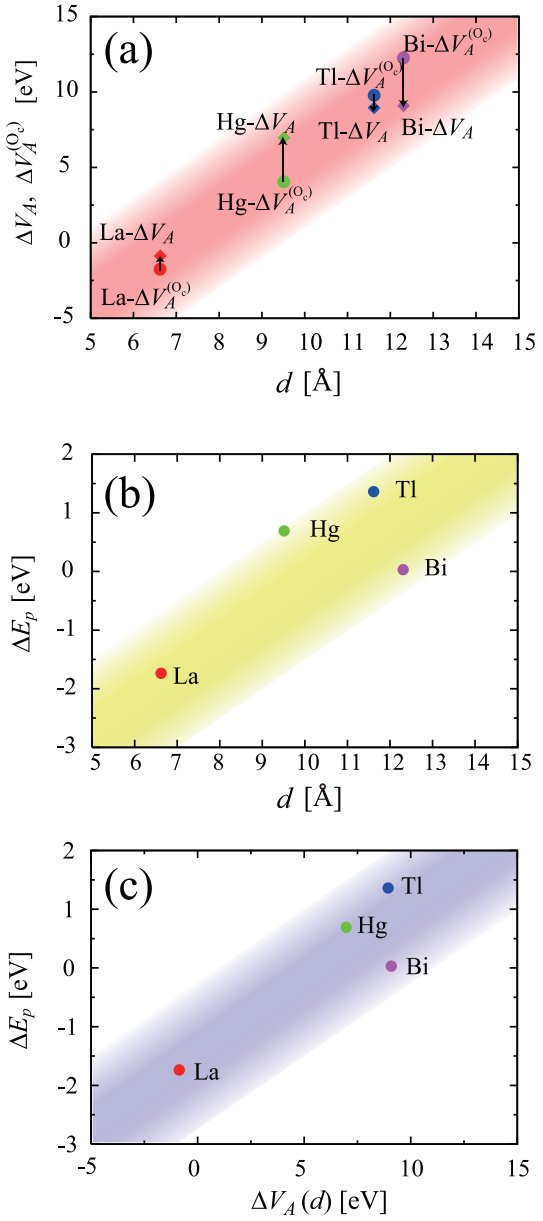

FIG. 12: (Color online) (a) $\Delta V_A^{(O_c)}$ (circles) and ΔV_A (diamonds) plotted against the layer separation d for La, Bi, Hg, and Tl cuprates. (b) The level offset, ΔE_p, between the in-plain p_σ and the apical oxygen p_z against the layer separation d. (c) The correlation between ΔV_A and ΔE_p.

from the effect of h_O (or ΔE_d), ΔE is positively correlated with ΔE_p and thus with ΔV_A, so that ΔV_A and T_c should be roughly correlated. In this sense, the so-called Maekawa's plot (Fig.2 of ref.[31]) is consistent with the present Fig.6. Also, a negative correlation between the occupancy of holes with $p_z - d_{z^2}$ character and T_c has been found in ref.[22], which is again consistent with the present view.

TABLE III: The values of ΔE_d (along with h_O), ΔE_p (along with d), and ΔE for La, Bi, Hg and Tl cuprates.

-	La	Bi	Hg	Tl
ΔE_d [eV]	0.064	0.12	0.39	0.39
h_O [Å]	2.41	2.46	2.78	2.71
ΔE_p [eV]	-1.7	0.030	0.89	1.4
d [Å]	6.6	12.3	9.5	11.6
ΔE [eV]	0.91	1.6	2.2	2.2

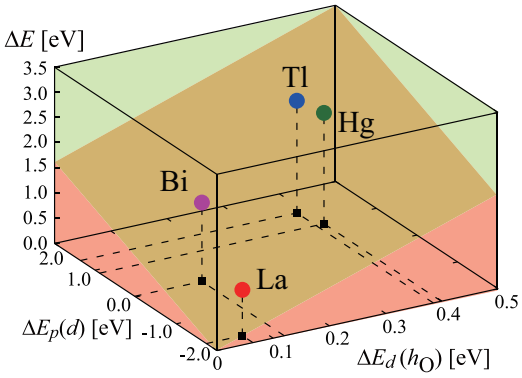

FIG. 13: (Color online) ΔE plotted against ΔE_p and ΔE_d for the four single-layered cuprates considered here. An oblique plane indicates a rough correlation between ΔE and $(\Delta E_p, \Delta E_d)$.

V. DISCUSSIONS

A. Validity of the present model

In the present study, we have adopted the LDA to derive the kinetic-energy part of the model Hamiltonian. The LDA calculation neglects some of the electron correlation effects, and our standpoint in the present study is that the remaining part of the electron correlation is dealt with in the FLEX calculation. One might suspect, however, that there might remain electron correlation effects, that are not taken into account in the present approach but can affect the accuracy of the evaluation of the level offset ΔE between $d_{x^2-y^2}$ and d_{z^2} Wannier orbitals. Our view on this point is the following. First, it is an experimental fact that the La cuprate has a square-like Fermi surface, while the Bi cuprate a rounded one[2]. This is accurately reproduced in the LDA, which strongly suggests that the d_{z^2} component is indeed strongly mixed around $(\pi, 0), (0, \pi)$, i.e., ΔE is small, in the La cuprate. Secondly, a detailed quantitative difference in ΔE will not affect the present conclusions. To see this, we have performed an LDA+U calculation to obtain the kinetic-energy part of the Hamiltonian, varying U from 0 to 6 eV. For La, the considerable d_{z^2}-character around $(\pi, 0), (0, \pi)$ persists even at $U = 6$, and the band that intersects the Fermi level is only slightly changed, although ΔE somewhat increases with U. On the other hand, for Hg ΔE is greatly enhanced by U, but

this does not significantly affect the $d_{x^2-y^2}$ main band, since the d_{z^2} character is already absent at $U = 0$. Applying FLEX to these LDA+U models will result in a double counting of the electron correlation effects because FLEX takes account of the first-order terms, but if we took, for the sake of comparison, the obtained ΔE, we would find that a considerable difference in λ between La ($\lambda \simeq 0.5$) and Hg ($\simeq 0.8$) is still present even if we adopt the modified values of ΔE.

B. Possibility of higher-T_c materials

A consequence of our study is that superconductivity in the single-layered cuprates is optimized when the system has a single-band nature. In such a case (as in Hg cuprate), the Fermi surface is rounded due to the effect of the Cu 4s orbital. As mentioned in sectionII A, the square shaped Fermi surface would be more favorable for superconductivity for single-orbital systems. For this very reason even the $HgBa_2CuO_{4+\delta}$ is not fully optimized as a single-layered material. Indeed, the hypothetical La cuprate having a large ΔE but with a Fermi surface similar to that in the original La gives a larger λ in the Eliashberg equation as we have seen in section III D. So we have a bit of a dilemma, since it would be difficult to get rid of the effect of the Cu 4s orbital *as far as the cuprates are concerned*. Conversely, however, we can seek for other materials in which the 4s orbital is not effective. An example is a single-band system consisting of d_{xy} orbitals, where the hybridization between d_{xy} and 4s orbitals is forbidden by symmetry. In fact, a possible way of realizing a single-band d_{xy} system has been proposed in ref.[32]. Provided that such a system has the band width and the electron-electron interaction strength similar to those in the cuprates (since too strong or too weak a correlation will degrade superconductivity), it can possibly give even higher T_c.

VI. CONCLUSION

To summarize, we have studied a two-orbital model that considers both $d_{x^2-y^2}$ and d_{z^2} Wannier orbitals in order to pinpoint the key factors governing the material dependence of T_c within the single-layered cuprates. We conclude that the d_{z^2} orbital mixture on the Fermi surface is significantly degrades superconductivity. Since the energy difference ΔE between the d_{x^2-y2} and the d_{z^2} governs the mixture as well as the shape of the Fermi surface, we identify ΔE as the key parameter in the material dependence of T_c in the cuprates. Since the mixing effect supersede the effect of the Fermi surface nesting, a small ΔE results in a suppression of T_c despite a square shaped Fermi surface. ΔE is then shown to be determined by the energy difference ΔE_d between the two Cu3d orbitals, and the energy difference ΔE_p between the $O_{\rm plane}$ p_σ and $O_{\rm apical}$ p_z, both of which are affected by the lattice structure. ΔE_d is a crystal field splitting, which is mainly determined by the apical oxygen height, while ΔE_p is found to be primarily governed by the interlayer separation d. The materials that have highest T_cs within the single-layered cuprates, Hg are Tl systems, indeed have ΔE large enough to make them essentially single-band. On the other hand, there is still room for improvement if we can suppress the effect of the Cu 4s mixing that makes the Fermi surface rounded, which may be realized in non-cuprate materials with U similar to the cuprates in magnitude.

VII. ACKNOWLEDGMENTS

We are grateful to O. K. Andersen and D. J. Scalapino for fruitful discussions. The numerical calculations were performed at the Supercomputer Center, ISSP, University of Tokyo. This study has been supported by Grants-in-Aid for Scientific Research from MEXT(Grant No.23340095:R.A.) of Japan and from JSPS(Grant No.23009446:H.S., No.21008306:H.U., and No.22340093:K.K. and H.A.).
